ROTATING-BEAM FATIGUE TESTS OF NOTCHED AND UNNOTCHED 7075-T6 ALUMINUM-ALLOY SPECIMENS UNDER

STRESSES OF CONSTANT AND VARYING AMPLITUDES

By Herbert F. Hardrath, Elmer C. Utley, and David E. Guthrie

### SUMMARY

Unnotched and notched rotating-beam specimens made of 7075-T6 aluminum alloy were tested under constant and varying stress amplitude. Static mechanical properties and constant-amplitude fatigue tests of unnotched specimens yielded results higher than average for the material. Fatigue tests of notched specimens indicated the material was more notch sensitive than indicated by other data. Lives obtained in fatigue tests with variable amplitude were generally less than expected on the basis of the linear cumulative damage rule.

#### INTRODUCTION

The estimation of the expected life of a given part of an aircraft structure depends, among other things, upon considerations of the size and shape of the part, the loading history to which it may be subjected, and the fatigue properties of the material from which it is made. Reliable rules for combining these pieces of information and applying them to a design case are lacking at present. Consequently, many fatigue tests are conducted on actual parts in order to prove the adequacy of the design from the fatigue standpoint.

The Langley Research Center of the National Aeronautics and Space Administration is conducting research intended to provide data which will help to formulate the design rules which are needed before a structure may be evaluated for its fatigue behavior without extensive tests. The present paper presents results of a systematic series of tests conducted on notched and unnotched 7075-T6 aluminum-alloy rotating-beam specimens under constant and variable stress amplitudes. In most cases a given test was repeated 3 to 10 times in order to provide information on scatter. The testing techniques, equipment, data, and elementary analysis are discussed.

## SYMBOIS

$K_{\mathbf{N}}$	Neuber technical stress concentration factor
$\kappa_{ m T}$	theoretical stress concentration factor
n	number of load cycles applied at a given stress level
Δn	increment in number of load cycles applied at a given stress level
N	number of cycles of load required to produce failure
$S_{\min}$	minimum stress amplitude, ksi
Smax	maximum stress amplitude, ksi
ΔS	increment in stress amplitude, ksi
ρ	radius of curvature of notch, in.
ρ'	material constant, in.
ω	included angle in notch, radians

## SPECIMENS

All test specimens were cut from 40 ten-foot lengths of 7075-T6 extruded aluminum-alloy rod 1/2 inch in diameter. One tensile test specimen and one compressive test specimen were cut from each end of each rod. The tensile test specimens were standard 0.3-inch-diameter specimens prepared according to reference 1. Compressive test specimens were  $1\frac{1}{2}$  inches long with ends ground parallel to each other and normal to the axis; the cylindrical surfaces were left as received.

Twenty-five fatigue-test specimen blanks  $3\frac{3}{4}$  inches long were cut

from each rod. To be consistent with a previously used numbering system, each blank was identified by the letter B to represent 7075-T6 aluminum alloy, a number between 1 and 40 to identify the rod from which the blank was cut, the letter F for fatigue specimen, and a number between 1 and 25 to identify the location of each specimen within the rod from which it was cut.

Unnotched fatigue specimens were machined to the dimensions shown in figure 1. The procedures used for machining unnotched specimens were identical with those used for preparing 2024-T4 specimens in reference 2. Briefly, machining was in several steps, each step removing less material than the preceding step. In order to assure that light cuts were taken, all machining was done with the specimens mounted on lathe centers with no torque-transferring device except the friction on these centers. Polishing was done in a superfinishing machine in five steps, each at right angles to the previous step. The last two polishing steps used 0.5-micron chromic oxide polishing agent suspended in mineral oil applied in metallurgical polishing broadcloth. The final step was in the longitudinal direction and produced a surface which was expected to be reasonably free of work hardening. The quality of finish was approximately the same as that of the 2024-T4 specimens tested in reference 2. (The estimated surface profile was 2 to 4 microinches root mean square.)

To cover a range of notch severities, notched specimens with three different root radii were prepared according to the dimensions shown in figure 1. The specimens with 0.094-inch radius were machined with a 3/16-inch-diameter milling tool rotated about an axis perpendicular to the axis of the specimen. (See fig. 2.) Manual feed was used and the tool was removed before it began to chatter. A uniformly smooth surface with final tool marks in the longitudinal direction was obtained. Polishing was done in two steps with 0.5-micron chromic oxide on a cord made up of several plies of knitting yarn. In the first step the yarn was rotated very slowly by hand while the specimen was rotated at about 260 revolutions per minute. In the second step the yarn was rotated by a motor at several hundred revolutions per minute while the specimen rotated at 25 revolutions per minute. Both operations were done with the aid of the apparatus shown in figure 3.

The specimens with 0.010-inch and 0.0032-inch root radii were machined in a lathe by using a carefully ground tool. Polishing was similar to that for specimens with 0.094-inch radius except that cotton threads were used and smaller weights were applied.

Each specimen was examined for surface irregularities and was used only if the surface was free of scratches, voids, and so forth. Diameters were measured and the notch radii were checked in a toolmaker's microscope.

Fatigue specimens were tested in 9 conventional 200-inch-pound capacity R.R. Moore rotating-beam fatigue-testing machines operating at 8,000 revolutions per minute. Three of these machines were equipped with special loading devices which varied the applied load continuously for variable-amplitude tests.

Two of the loading units were modified versions of units used for tests reported in reference 2. These units are shown schematically in figure 4(a). The device is simply a cam-driven lever B which pivots at a fulcrum F and stretches a calibrated spring S attached to the loading yoke of the machine. The cam drive derives its power through gear boxes G1 and G2 from the motor M which turns the specimen A to insure positive synchronization between cam and specimen. This feature is the only significant change made to this equipment since it was used for the tests reported in reference 2. Adjustment of the position of the pivot on the beam produced different displacements in the spring for a given displacement of the cam. The adjustment of the turnbuckle T introduced an initial load in the system. Both adjustments were made to select various combinations of minimum and maximum load and consequently minimum and maximum stress amplitudes. Counterweights W were attached to each housing to allow application of low stresses. Dial gage D was used to measure spring deflections.

Two different cams C were used to provide two loading spectra: cam A produced stress amplitudes which were modulated sinusoidally with time and cam B produced stress amplitudes modulated according to an exponential function. Figure 5 presents typical time histories of stresses produced by each of these cams. Departure from the exponential function of cam B occurred at high stresses because a follower with a 1/2-inch radius was used in the lever. Thus, the sharp point on the cam was effectively rounded off. Although the cam speed was adjustable with respect to the speed of the specimen in several steps, all tests were conducted with the cam making one revolution for each 10,000 revolutions of the specimen.

The third loading device, shown schematically in figure 4(b), was designed to apply stresses according to the gust-frequency spectrum. (See ref. 3.) The main features which make this system different from the one just described are: (1) the load comes from a poise P rolling along a pivoted track, (2) the cam C is shaped to apply maximum force when the cam radius is a minimum to eliminate rounding off the sharp point even though a follower of finite radius was used, (3) the entire machine stops each time the cam makes one complete revolution instead of operating continuously, and (4) another gear box G3 with 1:1 and 10:1 gear ratios is mounted between the motor and specimen housings.

Since the cumulative gust-frequency spectrum (ref. 3) is essentially a straight line extending over several log cycles when plotted on semilog paper, it is impossible to represent the complete spectrum on a cam of reasonable size. In order to overcome this difficulty, the cam was designed to reproduce a segment of the complete curve and successive segments were used to represent the entire spectrum in each test. one cam revolution, the machine stopped, the relative speed of specimen and cam was changed by a factor of 10, the weight hanging directly below the loading yoke was changed, and the machine restarted. These adjustments were made after each cam revolution until the entire spectrum was applied and then the entire process was repeated until failure occurred. Figure 6 illustrates the gust-frequency spectrum and a typical cumulative frequency spectrum applied during one complete program in the present Segment A was applied by rotating the cam once for 105 revolutions of the specimen while the stress amplitude in the specimen varied between 2 and 10 ksi. Segment B was applied by rotating the cam once for 104 revolutions of the specimen while the stress amplitude varied between 10 and 18 ksi, and so forth. The ratio 1,000:1 between specimen speed and cam speed was obtained by reducing the rotational speed of the specimen by a factor of 10 at gear box Gz (shown in fig. 4(b)). A solenoid release mechanism L was provided to remove the load when the power to the motor was interrupted. This device prevented application of unwanted transient stresses while the motor coasted to a stop.

For comparison, the cumulative frequency diagrams for the three stress spectra used are given in figure 7.

#### TESTS

Tensile and compressive tests were performed to obtain stress-strain curves for 80 tensile specimens and 80 compressive specimens. Ultimate tensile strength and elongation in a l-inch gage length were also measured on tensile specimens. Strains were measured with electromagnetic extensometers having a l-inch gage length for tensile tests and a 1/2-inch gage length for compressive tests.

Since all tests were conducted in rotating-beam fatigue testing machines, stresses were completely reversed in all tests. Constant-amplitude fatigue tests were conducted on specimens with each of the shapes shown in figure 1. Testing was done in the usual manner in the six units not equipped for variable-amplitude loading. However, in order to remove bias which might be introduced by a given machine, 10 sets of spindle housings were used, and each housing was used on 1 of the 10 tests performed at a given stress level on a given specimen configuration. Tests were conducted in the machine base that was available

at the start of a given test. Since the machine base has no moving parts except in the motor, no bias was expected from the fact that the machine bases were not systematically rotated in the test schedule. A random sequence of testing was used to eliminate time-dependent effects such as machine wear, specimen aging, and so forth. An exception to this rule occurred for notched specimens with 0.010-inch radius tested at 30 and 36 ksi. These stress levels were not planned in the original program and were, therefore, conducted at the end of the schedule, all within a few days.

Fatigue tests conducted with varying stress amplitudes were conducted on unnotched and 0.010-inch-radius notched specimens only. The same 10 spindle housings used for constant-amplitude tests were used in random sequence. Tests using cams producing sinusoidal or exponential distributions of stress amplitudes were started at the highest stress amplitude in the schedule. Since the increment in load applied to the specimen was fixed and slight variation in specimen diameters was present, the minimum stress amplitude in a given group of tests varied somewhat.

Tests with the gust-frequency spectrum were started at the lowest stress in each increment to minimize errors in loading which might occur if tests were started and stopped when the rate of change in stress was greatest. The weight of the carriage and the stationary weight were adjusted for each specimen; thus all tests in a given group were conducted at the same stress levels. In order to provide a variety of test conditions with the same loading device, the spectrum produced by the machine was modified arbitrarily. In the basic schedule the minimum stress amplitude applied was 2 ksi and each revolution of the cam produced an increment of 8 ksi to a maximum of 34 ksi. In another schedule, the first stress increment was omitted so that stress amplitudes varied between 10 ksi and 34 ksi. A third schedule was arranged to produce a stress increment of 5 ksi for each cam revolution. The minimum stress amplitude was 9 ksi and the maximum was 29 ksi. This change altered the slope of the gust-frequency curve, shown in figure 7, to 5/8 of the slope shown. The test condition would correspond to a design condition using a higher design load factor.

The alinement of each specimen-bearing housing assembly was checked with dial gage indicators. Specimens were not used if the eccentricity of the assembly was greater than 0.0015 inch.

## RESULTS AND DISCUSSION

## Mechanical Properties

The mechanical properties obtained in tension and compression tests are listed in table 1(a). Each value in the table is the average of 80 test results. The yield stresses and ultimate tensile strengths are considerably higher than specification values listed in reference 4.

A 12-inch-long piece of one of the rods was submitted to the Alcoa Research Laboratories (ARL) to verify the results. Mechanical properties and results of a chemical analysis performed by the ARL are listed in table 1(b). The mechanical properties are seen to be in good agreement with NASA values and the chemical analysis indicates satisfactory composition. Thus, the chemical composition of the material was within specification limits for 7075-T6 aluminum-alloy rod but the properties were somewhat better than average.

## Constant-Amplitude Fatigue Tests

The results of fatigue tests at constant stress amplitude are listed in table II. The corresponding S-N curves are presented in figure 8 for unnotched specimens and for specimens with 0.010-inch notch radius and in figure 9 for specimens with 0.094-inch and 0.0032-inch notch radius. The symbols in each figure represent the median of the numbers of cycles to failure for each group of specimens tested under identical conditions. The extent of scatter in life for each group is indicated by the ticks. The median values were chosen to represent each group of data because this is the simplest quantity which can be used in situations where some specimens fail and others do not.

The scatter for unnotched specimens is seen to be considerably greater than was found for 2024-T4 unnotched specimens tested in reference 2. However, the results fall within the scatter band presented for 7075-T6 unnotched rotating beams in reference 4. For comparison, the dashed curve in figure 8 represents the average curve for data in reference 4. The present results are generally above this curve. The runout stress, that is, the stress at which there is a 50-percent probability of failure in  $5 \times 10^8$  cycles, is approximately  $2^4$  ksi for unnotched specimens and 20 ksi, 9.6 ksi, and 6.3 ksi for notched specimens in order of increasing notch severity.

The scatter in results for tests of notched specimens (figs. 8 and 9) is about as great as that for unnotched specimens. The dashed curves drawn near the data for notched specimens with 0.010-inch and 0.0032-inch radii are the average curves given in reference 4 for rotating beam tests

of 7075-T6 aluminum-alloy specimens having notches with approximately 0.0002-inch radius.

The average curve for the present data for notches with 0.010-inch radius is very close to the dashed curve and the average of present data for notches with 0.0032-inch radius is well below the curve. Thus, the present material has somewhat greater than average fatigue strength in the unnotched specimens, but its notch sensitivity appears to be enough greater than average to produce lower than average fatigue strength in notched specimens.

The dot-dash curves in figures 8 and 9 are predictions of fatigue behavior made by a modified form of the Neuber technical stress concentration factor  $K_N$ . (See ref. 5.) The original Neuber equation is:

$$K_{N} = 1 + \frac{K_{T} - 1}{1 + \frac{\pi}{\pi - \omega} \sqrt{\frac{\rho'}{\rho}}}$$
 (1)

Later research (refs. 6 and 7) has shown that the influence of the included angle in the notch is considerably less, for angles in the range  $0^{\circ}$  to  $90^{\circ}$ , than that predicted by the Neuber formula. Equa-

tion (1) was, therefore, modified to the form 
$$K_N=1+\frac{K_T-1}{1+\sqrt{\frac{\rho'}{\rho}}}$$
 to

eliminate the effect of notch angle for these calculations. The material constant  $\rho'$  was adjusted empirically to a value of 0.002 inch to produce the best fit with the present data. The elastic stress concentration factors  $K_T$  for the notched configurations tested were 1.38, 3.0, and 5.0 for notch radii of 0.094, 0.010, and 0.0032 inch, respectively. The corresponding Neuber factors were 1.33, 2.37, and 3.23, respectively. The prediction made in this manner is lower than that for the data for specimens with the mildest notch but is very good for specimens with the two sharper notches.

### Variable-Amplitude Tests

The results of individual tests in which the stress amplitude varied are listed in table III. The test results are grouped by specimen configuration and loading spectrum in parts (a) to (d) of the table. Within

each part of the table, the results are grouped by the maximum stress amplitude  $S_{max}$  and by the increment in stress amplitude  $\Delta S$ . As indicated earlier, the increment in stress amplitude varied because of variations in specimen diameter. The resulting minimum stresses are given for each specimen and the value of  $\Delta S$  for each group is approximate. The median life for each group of tests is also listed in the table.

The results of tests conducted with the gust-frequency spectrum are listed in table III(e). These tests are grouped by minimum stress in the spectrum and the increment in stress obtained in one revolution of the cam.

The data have been analyzed according to the linear cumulative damage hypothesis. For the tests with sinusoidal and exponential stress modulation, the life of each specimen was divided into 12 equal increments  $\Delta n.$  The arithmetic mean of the maximum and minimum stresses for each of the stress increments was used to determine N, the number of cycles of load required to produce failure in a constant-level test at each stress increment. A value of  $\Delta n/N$  was obtained for each increment and these were

added to obtain  $\sum \frac{n}{N}$  for each test. The details of this computation

are described more completely in reference 2. Values of  $\sum \frac{n}{N}$  and the

median of these values within each group of tests are also listed in table III. Figures 10 to 12 present the results in graphic form. Data for unnotched specimens tested under sinusoidally and exponentially varying loading spectra are presented in figure 10. Similar data for notched specimens are presented in figure 11 and data for notched specimens tested with the gust-frequency spectrum are given in figure 12.

The logarithmic scale was chosen for  $\sum \frac{n}{N}$  because this quantity is a measure of life of specimens and fatigue lives are conventionally plotted on a log scale. The symbols represent the median of  $\sum \frac{n}{N}$  for each group and the scatter is indicated by the ticks. The percentage scatter in  $\sum \frac{n}{N}$  should be expected to be about as great as that in the lives of specimens loaded at constant amplitude. Most of the present tests involved stresses near the run-out stress where the scatter is usually greatest in constant-level tests. Thus, the scatter in  $\sum \frac{n}{N}$  shown is

not surprising.

In general, the number of tests in each group is too small to permit a critical assessment of scatter, but results of tests for notched specimens were subject to less scatter than were unnotched specimens tested under similar loading conditions. There is also some indication that scatter increased as the maximum stress decreased. The scatter in results of tests using the gust-frequency spectrum was surprisingly small.

The median values of  $\sum \frac{n}{N}$  were less than 1.0 for all groups of

tests on notched specimens. Median values of  $\sum \frac{n}{N}$  for unnotched speci-

mens were less than 1.0 in 12 of the 18 cases. On the whole, this observation is in agreement with results of other tests of rotating-beam specimens tested with stresses varying in amplitude. A contributing fac-

tor for the occurrence of failure when  $\sum \frac{n}{N}$  is less than 1 is probably

the damage caused by stresses below the run-out stress after cracks form. (See ref. 8.) Fatigue cracks cause higher stress concentrations than were present previously; thus, the minimum stress for which damage is to be expected is decreased. Such damage is, of course, not evaluated in

the calculation of  $\sum_{n=1}^{\infty} \frac{n}{N}$ .

Inspection of figures 10 and 11 reveals no systematic variation in  $\sum \ \frac{n}{N} \ \mbox{with stress level or shape of spectrum.} \ \ \mbox{This condition is in}$ 

contrast to what appeared to be a systematic variation in  $\sum \frac{n}{N}$  with

shape of spectrum observed in reference 2. It is possible that the effect noted in reference 2 was the result of a potential variation in the speed with which the specimen was driven while a separate motor drove the cam-lever system at essentially constant speed. The speed of the testing machine is somewhat slower when the load on the specimen is high. This speed change was probably greater for the sinusoidal cam than for the exponential cam because more time was spent at high loads and more of the inertia in the system was dissipated before the speed again increased. Slowing down the specimen while the load applied to the housings is high resulted in fewer than the proper number of cycles at high stress. Since this variation in speed was not evaluated, it could not be accounted for in the analysis of the results. Thus, the computed

value of  $\sum \frac{n}{N}$  was higher than it would have been if the effects of speed change on the stress spectrum had been known. The synchronized loading apparatus introduced in the present tests assured that the desired loading was applied and this condition seems to have eliminated the apparent effect of spectrum shape which was noted in reference 2.

The scatter in results of tests with the gust-frequency spectrum was surprisingly small. The mean values of  $\sum \frac{n}{N}$  for the three groups of tests were also grouped closely about a value of approximately 0.4.

### CONCLUDING REMARKS

Static tests and fatigue tests with constant and varying stress amplitudes have been conducted on 7075-T6 extruded aluminum-alloy bar stock. The static tensile and compressive properties were found to be substantially higher than specification values for this alloy. Results of constant-amplitude fatigue tests of unnotched specimens were subject to considerable scatter but in general were higher than mean values of data presented previously. Results of constant-level fatigue tests of notched specimens indicated somewhat higher notch sensitivity than was expected on the basis of previous information. Results of variable-amplitude fatigue tests of unnotched and notched specimens were analyzed according to the linear cumulative damage hypothesis. The values of the

summation of cycle ratios  $\sum \frac{n}{N}$  thus obtained tended to be less than 1 and did not appear to be affected by the shape of spectrum used. The

scatter in life under variable-amplitude stresses was of the same order as that under constant-amplitude stressing.
